Abstract
Purpose – The purpose of this paper is to optimize the design of charging station deployed at the terminal station for electric transit, with explicit consideration of heterogeneous charging modes.

Design/methodology/approach – The authors proposed a bi-level model to optimize the decision-making at both tactical and operational levels simultaneously. Specifically, at the operational level (i.e. lower level), the service schedule and recharging plan of electric buses are optimized under specific design of charging station. The objective of lower-level model is to minimize total daily operational cost. This model is solved by a tailored column generation-based heuristic algorithm. At the tactical level (i.e. upper level), the design of charging station is optimized based upon the results obtained at the lower level. A tabu search algorithm is proposed subsequently to solve the upper-level model.

Findings – This study conducted numerical cases to validate the applicability of the proposed model. Some managerial insights stemmed from numerical case studies are revealed and discussed, which can help transit agencies design charging station scientifically.

Originality/value – The joint consideration of heterogeneous charging modes in charging station would further lower the operational cost of electric transit and speed up the market penetration of battery electric buses.

Keywords Battery electric bus, Charging station design, Vehicle scheduling, Bi-level model, Heterogeneous charging modes

1. Introduction

Electric transit is considered as the key to the world’s clean transport future due to its high energy efficiency, zero emissions (Lajunen, 2014; Jin et al., 2015; Xu et al., 2021; Qu et al., 2020; Zhang et al., 2020; Zhang et al., 2021) and shareability (Gao et al., 2021; Bie et al., 2020; Meng and Qu, 2013; Wang et al., 2018). Compared with diesel buses, battery electric buses (BEBs) are able to improve energy efficiency by 50% and reduce greenhouse gas emissions by 98.36% (Mahmoud et al., 2016). During the past decade, the public transit is electrified step by step. For example, in the USA, the share of BEBs in the bus market increased rapidly from 2% in 2007 to nearly 20% in 2015 (Neff and Dickens, 2016); in Europe, the percentage of BEBs on the sales volumes of city buses is up to 10% by 2019, and this number rises up to around 20% in 2020. Undoubtedly, transit electrification is becoming an unstoppable trend.

Compared with diesel buses, the driving characteristics and refueling manner of BEBs are distinct. Specifically, BEBs generally have a much shorter operational range than buses powered by other energy sources, resulting in users’ “range anxiety” (Lebeau et al., 2016; Masmoudi et al., 2018; Qin et al., 2016; Li et al., 2019). To ensure normal operations, the consumed electricity must be replenished by either battery swapping or battery recharging (Li, 2013; Huang and Zhou, 2015; Wang et al., 2017; Tang et al., 2019; Liu and Ceder, 2020; Rinaldi et al., 2020). Unfortunately, instead of mitigating this disadvantage, lack of sufficient charging facilities further aggravates it (An, 2020). However, if sufficient charging facilities are deployed, it may cause severe budget burden for transit system. Meanwhile, charging modes also affect the charging efficiency as well as the infrastructure installation cost. Specifically, compared with normal charging, the fleet size can be reduced significantly through improved charging efficiency.

by adaptation of fast charging mode, but it also causes higher infrastructure installation cost. Therefore, how to design the charging station, trading off charging availability, charging efficiency and limited budget become an important issue in transit electrification. To this end, we aim at studying the optimal design of charging station deployed at the terminal station for electric transit in this paper. To be specific, we propose a bi-level model, where the lower-level model optimizes the scheduling of BEBs given the design of charging station, including the number of charging facilities of different charging modes (i.e. fast charging and normal charging); the upper-level model optimizes the design of charging station with explicit consideration of multiple charging modes. In the bi-level approach, the lower-level problem, i.e. optimal scheduling of BEBs, is the key and difficult part of the work. Therefore, we next present the relevant studies in the realm of vehicle scheduling.

Bus scheduling problem consists of assigning buses to serve a series of timetabled trips with the objective of minimizing fleet size and/or operational costs. It is an extension of the well-known vehicle scheduling problem (VSP), which has been extensively studied in the literature (Marković et al., 2015; Schöbel, 2017). Generally speaking, VSP can be categorized into two groups: the single-depot VSP (SDVSP) (Paixão and Branco, 1987; Freling et al., 2001; Kang et al., 2019) and the multiple-depot VSP (MDVSP) (Dell’Amico et al., 1993; Kliewer et al., 2006). Over the years, many varieties and extensions of VSP have been proposed to incorporate the real-world constraints and conditions, including VSP with multiple vehicle types (Ceder, 2011), VSP with route constraints (VSP-RC) (Bunte and Kliewer, 2009), the alternative fuel VSP (AF-VSP) (Li, 2013; Adler, 2014) and electric VSP (E-VSP) (Wen et al., 2016). Among these varieties, VSP-RC, AF-VSP and E-VSP are strongly motivated by electric vehicles. To accounting for the specifics of electric vehicles, route duration or route distance is constrained in VSP-RC (Haghani and Baníhashemi, 2002). If vehicles are allowed to be refueled at given recharging stations to prolong the total distance, that is AF-VSP. However, traditional AF-VSP only considers full charging and the charging time is set as fixed. Specifically, the vehicle’s fuel level is set to be full after visiting any recharging stations. For example, Li (2013) incorporated vehicle waiting time at charging stations into the model, and the charging time was simplified as fixed by considering battery swapping. Later, E-VSP was proposed, where partial charging was allowed and the charging time was usually assumed to be a linear function of the charged amount. Unfortunately, whereas much efforts have been made to deal with BEB scheduling, very little attention has been dedicated to explicitly modeling the design of charging station for electric transit, with full consideration of multiple charging modes. It will cause unforeseen operational cost when promoting transit electrification.

In light of the above literature, this paper would employ the latest study in electric vehicle scheduling to study the optimal design of charging station, and the bi-level solution approach is adopted to fix this problem. Numerical case studies were conducted to validate the applicability of the proposed model. It reveals that it is a cost-efficient choice to deploy sufficient charging facilities at the terminal station as the unit cost of charging facilities per day is much lower than that of BEBs.

Our key contributions from a theoretical and practical point of view can be summarized as follows:

• We are, to our best knowledge, the first to formulate and solve charging station design problem with explicit consideration of multiple charging modes and their corresponding effect on battery capacity fading.

• A number of managerial insights stemmed from the numerical case study are outlined, which can serve as a solid theoretical foundation for more cost-efficient charging station design.

The rest of this paper is organized as follows. Section 2 presents the problem formulation, i.e. a bi-level model. Section 3 elaborates the proposed solution approach for solving the problem. The numerical cases are conducted in Section 4. Conclusions are summarized in Section 5.

2. Mixed charging station design problem

2.1 Problem description

In this section, a single-terminal transit network is considered to define the optimization problem of charging station design, as depicted in Figure 1. BEBs depart from the terminal station to operate a sequence of scheduled round-trips, denoted as set V. For simplicity, we refer to the round-trip as trip for short from now. Charging facilities in mode \( q \in Q = \{q_1, q_2\} \) are deployed at terminal station with limited number \( C_q \) where \( q_1 \) indicates normal charging mode and \( q_2 \) indicates fast charging mode. For each trip \( i(\in V) \), the departure time \( s_i \), travel time \( e_i \), and the consumption of battery level relative to battery capacity, \( m \), are predefined and deterministic. The objective of this problem is to minimize the total cost of transit agency, including bus acquisition cost, charging fee, maintenance cost of BEB fleet and the cost incurred by the deployment of charging facilities. Therefore, the operators shall make decisions at both tactical and operational levels. To be specific, at the tactical level, the number of charging facilities in each type deployed at the terminal station should be optimized and the vector of decision variables at this level is denoted by \( C \triangleq \{C_q|q \in Q\} \). At the operational level, the operators shall make decisions on: how to assign BEBs to serve a series of trips satisfying the minimal battery level constraint and how to optimize recharging schedule considering limited charging facilities (i.e. given specific charging station design). The
Heterogeneous charging modes
Le Zhang, Ziling Zeng and Kun Gao

2.2 Lower-level problem: optimal scheduling of battery electric bus fleet

The objective of the lower-level model is to minimize total operational cost, including bus acquisition cost, charging fee and maintenance cost within one day, where the maintenance cost is mainly incurred by battery degradation. It is worth to note that the total charging fee is constant in our model, as it is related to the predefined trip service, which is fixed and independent of BEB schedule. Therefore, the objective function is simplified as the sum of bus acquisition cost and maintenance cost. The vector of decision variables at the operational level, \( X \), can be defined as \( X = \{\bar{\delta}_{ij}, \mu_{aq}\} \) \( i \in V, t \in T, q \in Q \), where:

- \( \bar{\delta}_{ij} \in \{0, 1\} \): set to one if BEB serves trips \( i \) and \( j \) consecutively, where trip \( i \) begins earlier than trip \( j \); and to zero otherwise, \( i \in V \cup O, j \in V \cup D, i \neq j \). Here \( O \) denotes a virtual trip that every bus must serve before its first real trip, and \( D \) denotes another virtual trip that each BEB serves after completing the last real trip of a day and being fully charged. The two notations are defined for the convenience of modeling work. The virtual trips’ travel times and electricity consumption are all set to zero:

- \( \mu_{aq} \in \{0, 1\} \): set to one if BEB begins to charge with charging mode \( q \) at time step \( t \) after finishing trip \( i \) and before serving the next trip, and to zero otherwise, \( i \in V, t \in T, q \in Q \).

- \( \phi_{aq} \in \{0, 1\} \): set to one if BEB is under charging with charging mode \( q \) at time step \( t \) after finishing trip \( i \) and before serving the next trip, and to zero otherwise, \( i \in V, t \in T, q \in Q \).

In this model, we make the following assumptions:

- **Assumption 1**: The time is discretized with the unit time as 10 min. The time for full charge in mode \( q_1 \) (i.e. normal charging) and mode \( q_2 \) (i.e. fast charging) are 2 h (i.e. 12 time steps) and 10 min (i.e. 1 time step), respectively.

- **Assumption 2**: BEBs are fully charged when departing from the original depot, and are charged back to full when returning to destination depot.

- **Assumption 3**: After finishing one trip, BEB can either be charged for one time and charged to full or serve the next trip consecutively without any charging activity.

The lower-level model [P1] can be formulated as:

\[
\min_{X} \sum_{q \in Q} C_q \cdot \delta_{Oq} + \sum_{i \in V} \sum_{t \in T} \sum_{q \in Q} \mu_{aq} d_q(SOCi, 1) \tag{1a}
\]

Subject to:

\[
\sum_{t \in T} \delta_{ij} = 1, \quad \forall j \in V \tag{1b}
\]

\[
\sum_{j \in V \cup O} \delta_{ij} - \sum_{j \in V \cup O} \delta_{ji} = 0, \quad \forall i \in V \tag{1c}
\]

\[
\sum_{i \in T} \sum_{q \in Q} \mu_{aq} \leq 1, \quad \forall i \in V \tag{1d}
\]

\[
(1 - \sum_{t \in T} \sum_{q \in Q} \mu_{aq}) M + \sum_{t \in T} \sum_{q \in Q} \mu_{aq} \cdot t \geq s_i + e_i, \quad \forall i \in V \tag{1e}
\]

\[
\sum_{t \in T} \phi_{aq} \leq C_q, \quad \forall t \in T, q \in Q \tag{1f}
\]

\[
- (1 - \mu_{aq}) M + F(SOC_i, q_1) \leq \sum_{t \in T} \psi_{aq} (t + F(SOC_i, q_1)) - (1 - \mu_{aq}) M + F(SOC_i, q_1), \quad \forall t \in T, i \in V \tag{1g}
\]

\[
- (1 - \mu_{aq}) M + F(SOC_i, q_2) \leq \phi_{aq}, \quad \forall t \in T, i \in V \tag{1h}
\]

\[
1 - m_i - (1 - \delta_i) M \leq SOC_i \leq 1 - m_i + (1 - \delta_i) M, \quad \forall i \in V \tag{1i}
\]

\[
SOC_i \geq lb, \quad \forall i \in V \tag{1j}
\]

\[
SOC_i \leq SOC_i - m_j + (1 - \delta_i) M + M \sum_{t \in T} \sum_{q \in Q} \mu_{aq}, \quad \forall i, j \in V \tag{1k}
\]

\[
SOC_i \geq SOC_i - m_j - (1 - \delta_i) M - M \sum_{t \in T} \sum_{q \in Q} \mu_{aq}, \quad \forall i, j \in V \tag{1l}
\]

\[
d_q(SOC_i, 1) = \frac{2 \times \xi(SOC_i, 1) \times (1 - SOC_i)}{X} W \gamma(q), \quad \forall i \in V, q \in Q \tag{1m}
\]

\[
s_j \geq s_i + e_i - (1 - \delta_i) M - M \sum_{t \in T} \sum_{q \in Q} \mu_{aq}, \quad \forall i, j \in V \tag{1n}
\]

\[
s_j \geq \sum_{t \in T} \mu_{aq} \cdot t + F(SOC_i, q_1) - (1 - \delta_i) M - \left(1 - \sum_{t \in T} \mu_{aq}\right) M, \quad \forall i, j \in V \tag{1o}
\]

\[
s_j \geq \sum_{t \in T} \mu_{aq} \cdot t + F(SOC_i, q_2) - (1 - \delta_i) M - \left(1 - \sum_{t \in T} \mu_{aq}\right) M, \quad \forall i, j \in V \tag{1p}
\]
In the above model, the objective function (1a) is to minimize the total operational cost over the operation hours of one day, including bus acquisition cost and maintenance cost, where \( \tilde{v} \) denotes the unit acquisition cost of BEB per day, and \( d_{q} \) indicates the cost incurred by battery degradation with the state of charge (SOC) from \( \text{SOC} \) (i.e. the SOC of BEB after just finishing trip \( i \)) to 100\% under charging mode \( q \). Constraints (1b) guarantee that each trip is served exactly once. Constraints (1c) represent covering and flow conservation. Constraints (1d) state that after trip \( i \), BEB may start charging in a certain time step with a certain charging mode. Constraints (1e) ensure that the starting time of charging activity after trip \( i \) should be no earlier than the end time of trip \( i \), where \( M \) is a sufficiently large number. Constraints (1f) guarantee the number of charging facilities used in each time step cannot exceed its capacity. Constraints (1g) ((1h)) state that \( F(\text{SOC}_{0}, q) \) (\( F(\text{SOC}_{0}, q_{2}) \)) time steps are occupied if normal (fast) charging operation is applied. Here \( F(\text{SOC}_{0}, q) \) indicates the number of time steps required to charge battery from \( \text{SOC}_{0} \) to full under charging mode \( q \); \( F(\text{SOC}_{0}, q_{2}) \) is always equal to 1 for all \( \text{SOC}_{i} \in (0, 1) \) due to assumption 1. Constraints (1i) indicate that BEB is fully charged when it departs from the original depot \( O \), where \( m_{i} \) means the consumption of battery level relative to battery capacity of trip \( i \). Constraints (1j) guarantee that SOC should be no smaller than a predefined lower bound \( lb \) to reduce range anxiety. Constraints (1k-n) record the dynamic SOC of BEBs if \( \delta_{q} = 1 \). Constraints (1o) define the function \( d_{p} \) where \( W \) indicates the battery acquisition cost; \( \chi \) is the end-of-life related parameter. The term \( \xi(\text{SOC}_{0}) \) denotes the corresponding battery capacity fading rate, borrowed from Lam and Bauer (2012); \( \gamma(q) \) refers to charging-mode related coefficient, where the coefficient of fast charging mode is larger than that of normal charging mode, i.e. \( \gamma(q_{1}) < \gamma(q_{2}) \). Constraints (1p-r) state the staking time of trip \( j \) should be no earlier than the ending time of trip \( i \) if \( \delta_{q} = 1 \) and \( \sum_{t \in T} \sum_{q \in Q} \mu_{tq} = 0 \); and the staking time of trip \( j \) should be no earlier than the ending time of charging operation applied after trip \( i \) if \( \delta_{q} = 0 \) and \( \sum_{t \in T} \sum_{q \in Q} \mu_{tq} = 1 \). Constraints (1s) indicate that buses are charged back to full when returning to destination depot.

We next present the exact mathematical form of function \( \xi(\text{SOC}_{0}) \):

\[
\xi(\text{SOC}_{i}) = \gamma_{1}\text{SOC}_{i,\text{dev}} \cdot e^{\gamma_{2}\text{SOC}_{i,\text{avg}}} + \gamma \leq e^{\gamma_{4}\text{SOC}_{i,\text{avg}}},
\]

wherewhere
\[
\text{SOC}_{i,\text{dev}} = \frac{1 + \text{SOC}_{i}}{2}, \tag{2b}
\]

Here the coefficients \( \gamma_{1}, \gamma_{2}, \gamma_{3} \) and \( \gamma_{4} \) are constant model parameters.

In this paper, we consider nonlinear charging profile, where SOC increases non-linearly with respect to the charging time, as presented in **Figure 2**. Specifically, the battery would undergo two phases, namely, CC phase and CV phase. In the first phase (i.e. CC phase), the charging current is held constant and hence the SOC increases linearly with time until the battery’s terminal voltage reaches the threshold. After that, the terminal voltage keeps constant (i.e. CV phase), thus resulting in the current decreasing exponentially and the growth rate of SOC decreasing with respect to the charging time. The pattern of SOC with respect to the charging time under normal charging mode can be approximated by piecewise linear function:

\[
\text{SOC}(t, q_{1}) = \begin{cases} 
0.8t & t \in [0, 1] \\
0.8 + 0.2(t - 1) & t \in [1, 2]
\end{cases}
\]

where \( t \) is in the unit of hour. Therefore, the number of time steps required to charge battery from \( \text{SOC}_{i} \) to full under normal charging mode can be calculated as follows:

\[
F(\text{SOC}_{i}, q_{1}) = \begin{cases} 
30(1 - \text{SOC}_{i}) & \text{if } \text{SOC}_{i} > 0.8 \\
6 + \frac{15}{2}(0.8 - \text{SOC}_{i}) & \text{if } \text{SOC}_{i} \leq 0.8
\end{cases}
\]

Here function \([a]\) returns the smallest integer that is no smaller than \( a \).

### 2.3 Upper-level problem: optimal design of charging station

The upper-level model can be formulated as follows:

\[
\min_{C} f_{[p2]} = \sum_{q \in Q} A_{q} C_{q} + f_{[p1]}(X, C)
\]

Subject to:
where $A_q$ indicates the unit installation cost of charging facility in mode $q$ amortized to one day, measured in $$/day, $g(\cdot)$ denotes the optimal lower-level solution for $X$ under a given design of charging station $C$, which is found by solving model [P1]. $f_{[P1]}(X, C)$ indicates the daily operational cost under a solution, where $X$ and $C$ are placed into a framework of the general label-correcting algorithm. For more details on the theory of CG, please refer to Merle et al. (1999). Briefly, model [P4] is solved by repeatedly solving (i) a restricted master problem with a subset of trip chains and (ii) a pricing subproblem to generate new trip chains with negative reduced costs. The restricted master problem is solved by commercial solvers directly (e.g. Cplex, Gurobi). The pricing problem is shortest path problem with resource constraint and solved by label-correcting algorithm with fully considering special problem aspects: minimal battery level and battery recharging. Each state is represented by a label, $(k, b)$, where $k$ is the last reached node and $b$ represents the corresponding battery level. The cost of label $(k, b)$ is $\bar{z}(k, b)$, representing the accumulative cost from original depot $O$. Now consider that both label $(k, b)$ and label $(k, \bar{b})$, label $(k, b)$ dominates $(k, \bar{b})$ if (1) $\bar{z}(k, b) < \bar{z}(k, \bar{b})$, and (2) $b > \bar{b}$, where at least one of above inequalities is strict. The label extension and dominance rule are placed into a framework of the general label-correcting algorithm to solve the pricing problem.

To generate feasible integer solution, we next propose a heuristic algorithm based upon the CG procedure to obtain near-optimal integer solutions. In the proposed heuristic algorithm, the inner procedure is the CG procedure; the outer procedure is the selection strategies used to obtain an integer solution.

Firstly, we modify constraint (6c) in model [P3] as:

$$\sum_{r \in R} U_{rq} \lambda_r \leq C_q, \quad \forall t \in T, \quad q \in Q$$

(8)

Initially, $C_q$ is constant and equal to $C_q^0$. Then the available number of charging facilities at each time step may decrease as the outer procedure proceeds in our heuristic algorithm. To be specific, every time the inner CG procedure stops, we select the trip chain (i.e. column) with the largest value of the decision variables $\lambda_r$. Then update $C_{q_t}$ and $V$ for a new iteration of the above process:

- if BEB is charged in time step $t$ under charging mode $q$ according to the selected trip chain, update $C_{q_t} \leftarrow C_{q_t} - 1$;
- if trip $t$ is served in the selected trip chain, update $V \leftarrow V/\beta_t$.

The algorithm terminates when all the trips are served.

3.2. A tabu-search method for solving upper-level model

The first step of the tabu search is to initialize a feasible initial solution to model [P2], denoted by $X^0 = \{C_q^0, C_q^0\}$. Then define a move as a change from a feasible solution $X$ to a new feasible solution, where the change can be one of the following: (i) $C_{q_t} \rightarrow C_{q_t} - 1$ or $C_{q_t} \rightarrow C_{q_t} + 1$; and (ii) $C_{q_t} \rightarrow C_{q_t} - 1$ or $C_{q_t} \rightarrow C_{q_t} + 1$. At each move, the CG-based heuristic algorithm presented in Section 3.1 is executed to find the BEB utilization schedule and recharging plan. The total cost $f_{[P2]}$ is then calculated. Define the neighborhood of $X$, $N(X)$, as the set of feasible solutions that can be obtained by making one move from $X$. Further define the tabu list, $TL$, as the list of inverse moves of those most recent moves performed. The maximum length of tabu list is denoted as $tabu\_size$. In each iteration, a move is made according to one of the following two rules:

- If no move in $N(X)$ can produce a lower total cost as compared to the best solution so far, set the current move
to the one in $N(X) \cap TL$ that produces the lowest total cost. Following this rule, a move is made even if it produces a higher cost than the best solution so far.

- If a move in $N(X) \cap TL$ produces a lower total cost than the best solution so far, set the current move to the lowest-cost move in $N(X)$.

The tabu list $TL$ is updated after each iteration. It is used to prevent the algorithm from returning to a solution attained in a previous iteration. The first rule finds the best neighboring solution that is generated not from any move in the tabu list. However, if a move in the tabu list can yield a better solution than the best one so far, that move is still selected according to the second rule. The algorithm ends when no better solution is found after max-tabu consecutive iterations.

### 4. Numerical cases

To validate our model, in this section we focus on a case study with the terminal denoted as terminal station A. Departing from terminal station A, five yet-to-be-electrified lines are studied. The lengths of the five lines are 11 km, 11.5 km, 12.6 km, 19.3 km and 16.8 km respectively. Their travel durations (terminal to terminal) are 80 min, 90 min, 110 min, 150 min and 130 min respectively. The timetables for these five lines are shown in Table 1. The technical parameters needed for this paper are obtained from Yutong ZK6850BEVG53, as specified in Table 2. Specifically, Yutong ZK6850BEVG53 is a kind of medium BEB, with vehicle length as 8.5 meters.

investigation reveals that, as the unit cost of charging facilities per day is relatively low as compared with that of BEBs, it is cost-efficient to deploy the charging facilities as more as needed so that the total cost of transit agency can be saved by reducing fleet size.

We also note that the SoC variation negatively affects battery aging rate: the larger the SoC variation is, the faster the battery degrades. Therefore, to prolong battery life, the operators are encouraged to charge BEBs as frequently as possible, instead of as late as possible. As a trade-off, when the charging facilities are relatively sufficient, the electric buses tend to be charged as frequently as possible, to achieve more cost saving by extending batteries’ lifespan.

We next examine the effect of the number of fast chargers on the optimal cost, as presented in Figure 4. Compared to normal charging, fast charging mode can reduce the fleet size largely due to its high charging efficiency, even though the installation cost of fast charging facilities is much higher than that of normal charging facilities. Therefore, the maximum number of fast chargers required is only 3 with the minimal operational cost at the lower-level as $1.05 \times 10^3$, as shown in Figure 4. The figure also reveals that the minimal total cost at the upper level ($1.14 \times 10^3$) occurs when the number of fast chargers is 3.

When mixed design of charging station is considered, the model reveals that the optimal charging station design is to install 2 fast chargers and 2 normal chargers, where the optimal total cost is $1.12 \times 10^3$. Even though the daily saving brought by mixed design of charging station is minor, i.e. only $20. However, this benefit cannot be overlooked over 10 years or more.

5. Conclusions

In this paper, we present a new mathematical formulation aimed at optimizing the design of charging station deployed at the terminal station for electric transit. To this end, a bi-level model is built with full consideration of the decision-making at both tactical and operational levels. Specifically, the lower-level model optimizes the scheduling of BEBs given the design of charging station, including the number of charging facilities under different charging mode (i.e. fast charging and normal charging), whereas the upper-level model optimizes the design of charging station given optimized BEB service sequence and charging plan at the lower level.

In the future work we plan to explore more realistic scenarios where the “full-charging” assumption is relaxed, i.e. partial charging among BEBs is allowed and the charging time depends on the amount of energy to be replenished following more realistic non-linear charging profile. Meanwhile, we would also plan to extend the transit network to the one with multiple terminals, explore more efficient solution approach with high quality, instead of using heuristic algorithm; consider agency budget for the installation of charging infrastructure and consider users’ psychological inertia (Gao et al., 2020).

Note

1 The result may deviate within a small range due to the variation of exchange rate.
